# Dicke's thought experiment

Prerequisite: two level atoms or 'spins' which couple to photons. An unexcited spin ( $|\downarrow\rangle$ ) can absorb a photon to become excited ( $|\uparrow\rangle$ ) and vice versa.

Consider an  $\uparrow$  spin which will emit a photon with a certain rate. If we bring a second unexcited spin ( $\downarrow$ ) close to it, will this change the emission properties?

Naive expectation: It will not as the second spin does not emit.

Quantum effects: The wavefunction for both spins is

$$\begin{aligned} |\uparrow\downarrow\rangle &= \frac{1}{\sqrt{2}} \left[ \frac{\{|\uparrow\downarrow\rangle - |\downarrow\uparrow\rangle\}}{\sqrt{2}} + \frac{\{|\uparrow\downarrow\rangle + |\downarrow\uparrow\rangle\}}{\sqrt{2}} \right] \\ &= \frac{1}{\sqrt{2}} \left[ \underbrace{|s\rangle}_{\text{dark}} + \underbrace{|t_0\rangle}_{\text{bright}} \right] \end{aligned}$$

- ▶ A photon will now only be emitted with probability half
- ▶ Dicke showed that the average rate of emission does not change as the triplet radiates at twice the rate
- ▶ Building on this quantum picture, he identified states of  $N$  spins with the highest rate of emission – ‘superradiance’
- ▶ Note that observation of emitted photon will collapse the spin wavefunction to  $|t_{-1}\rangle$

# The Dicke model

Minimal model for spins interacting with photons:

- ▶ Spins are placed within a cavity – quantised photon modes
- ▶ Only one mode is near resonance – ignore others
- ▶  $\underbrace{\lambda_{dB}}_{\text{size of spin}} \ll \underbrace{a}_{\text{spin-spin spacing}} \ll \underbrace{\lambda_{ph}}_{\text{photon wavelength}}$ 
  - ▶ Spins do not interact directly with one another
  - ▶ They couple to the photon mode as if they were all at the same point

Dicke Hamiltonian:

$$\begin{aligned} H &= \omega_0 a^\dagger a + B \sum_{i=1}^N \hat{S}_i^z + g \sum_{i=1}^N \left[ \hat{S}_i^- a^\dagger + \hat{S}_i^+ a \right] \\ &= \omega_0 a^\dagger a + B \hat{S}_{tot}^z + g \left[ \hat{S}_{tot}^- a^\dagger + \hat{S}_{tot}^+ a \right]. \end{aligned}$$

# The Dicke model – states

$$H = \omega_0 a^\dagger a + B \hat{S}_{tot}^z + g \left[ \hat{S}_{tot}^- a^\dagger + \hat{S}_{tot}^+ a \right].$$

$$|S_{tot}, m_{tot}, n_{ph}\rangle \xrightarrow{H} |S_{tot}, m_{tot} + 1, n_{ph} - 1\rangle$$

$$|S_{tot}, m_{tot}, n_{ph}\rangle \xrightarrow{H} |S_{tot}, m_{tot} - 1, n_{ph} + 1\rangle$$

Conserved quantities:  $S_{tot}, m_{tot} + n_{ph}$

‘Superradiance’: In a system of  $N$  spin-1/2 spins, the rate of photon emission highest from  $|S_{tot} = N/2, m_{tot} = 0\rangle$ .

- seen in BECs, magnons, cavity QED experiments, etc.

‘Subradiance’<sup>1</sup>: No emission from any state with  $S_{tot} = 0$ .

- long lived states with potential for use as quantum memories

---

<sup>1</sup>Scully, PRL 2015 and others

# Realising Dicke's thought experiment

Realised only in 2014<sup>1</sup>:  $N = 2$  spins in a cavity. Measured quantity: density matrix of outgoing photon

(Inverse) time scales in a Dicke model experiment

- ▶  $\tilde{g}$ : rate of spin-photon coupling
- ▶  $\kappa$ : rate of loss of photon from cavity
- ▶ spin-spin interaction, non-radiative loss, etc.

To realise Dicke's thought experiment, we need:

$\kappa \gg \tilde{g} \gg$  all other rates – 'lossy cavity limit'

If the spins emit photon(s), they are not reabsorbed. Rather, they 'immediately' leave the cavity. They can then be measured outside as they exit the cavity.

---

<sup>1</sup>J. A. Mlynek et. al., Nature Communications 2014 

# Proposal to generate RVB states

Dicke's thought experiment as a Stern-Gerlach measurement:

- ▶ Initialise  $N$  spins in a direct product state
- ▶ Measure number of photons emitted – timescale:  $\tilde{g}^{-1}$
- ▶ Claim: null observation collapses spin wavefunction onto an RVB state
- ▶ Further claim: \*almost\* every outcome of this measurement leads to an RVB state

Two spin example:

- ▶ Initial state:  $|\uparrow\downarrow\rangle$
- ▶ Possible outcome for photon measurement: 0 or 1
- ▶ 0-measurement collapses wavefunction onto singlet

# Detecting null emission

Non-detection of photons is also a measurement in the quantum mechanical sense!

No detection  $\leftrightarrow$  no photon was emitted by the spins

Possible issues:

- ▶ Non-radiative decay of spins
- ▶ Photon leaves cavity through other mirror
- ▶ Initialisation in a direct product state may have errors

Current experiments already have the above issues under control<sup>1</sup>

- ▶ Technology for number detection at the single photon level
- ▶ High precision to avoid false readouts of null measurement

Possible test for RVB character – if a photon is pumped in, the RVB state cannot absorb it

---

## Radiation 'trapping'

$$H = \omega_0 a^\dagger a + B \hat{S}_{tot}^z + g \left[ \hat{S}_{tot}^- a^\dagger + \hat{S}_{tot}^+ a \right].$$

Note: a state of  $N$  (even) spin-1/2 spins can have  $S_{tot} = 0, 1, \dots, N/2$ .

Consider an initial state with one  $\uparrow$  spin and all others  $\downarrow$ .

$$|\psi_{init.}\rangle = |\uparrow\downarrow\cdots\downarrow\rangle$$

$$m_{tot} = -N/2 + 1 \longrightarrow S_{tot} = N/2 - 1, N/2$$

$$|\psi_{init.}\rangle = a_{N/2} |N/2, -N/2 + 1\rangle + a_{N/2-1} |N/2 - 1, -N/2 + 1\rangle$$

- ▶  $|N/2, -N/2 + 1\rangle$ : 'bright' state - can emit one photon and decay to  $|N/2, -N/2\rangle$
- ▶  $|N/2 - 1, -N/2 + 1\rangle$ : 'dark' state - cannot reduce  $m_{tot}$  any further  $\implies$  cannot emit

## 'Radiation trapping'

- ▶ Probability of emission:  $1/N$  – small for large  $N$
- ▶ Bright component:  

$$\frac{1}{\sqrt{N-1}} \left[ |\uparrow\downarrow \cdots \downarrow\rangle + |\downarrow\uparrow \cdots \downarrow\rangle + \cdots |\downarrow\downarrow \cdots \uparrow\rangle \right]$$
- ▶ Positive photon observation: spins collapse onto  $|\downarrow \cdots \downarrow\rangle$
- ▶ Null observation collapses spins onto

$$\hat{P}_{N/2-1} \left| \begin{array}{c} \uparrow \\ \downarrow \downarrow \downarrow \downarrow \downarrow \end{array} \right\rangle = \frac{1}{N} \left[ \left| \begin{array}{c} \text{excitation} \\ \downarrow \downarrow \downarrow \downarrow \end{array} \right\rangle + \left| \begin{array}{c} \text{excitation} \\ \downarrow \downarrow \downarrow \downarrow \end{array} \right\rangle + \left| \begin{array}{c} \text{excitation} \\ \downarrow \downarrow \downarrow \downarrow \end{array} \right\rangle + \left| \begin{array}{c} \text{excitation} \\ \downarrow \downarrow \downarrow \downarrow \end{array} \right\rangle \right]$$

– a 'resonating valence bond' state

- ▶ An excitation is 'trapped' – it is continually absorbed and reemitted coherently – does not escape outside the cavity
- ▶ Phenomenon of trapping known since the 1960's – however, RVB character has not been pointed before
- ▶ 'Weak' RVB – one valence bond shared among  $N$  spins

# Resonating Valence Bond state

- ▶ A linear combination of singlet arrangements – typically highly entangled wavefunction
- ▶ First proposed by Pauling for benzene
- ▶ Proposed ground states for ‘frustrated’ magnets: first suggested in the triangular lattice antiferromagnet<sup>1</sup>
- ▶ ‘Spin liquid’ wavefunction: first example of topological order<sup>2</sup>
- ▶ Precursor to high- $T_c$  superconductivity – ‘mean-field’ momentum space description<sup>3</sup>
- ▶ No ‘clean’ examples (except in organic chemistry) – e. g., S. Nascimbène et. al., PRL 2012 – a cold atoms realisation with 4 spins
- ▶ Required: RVB realisations that are amenable to doping, manipulations, etc.

# Strong RVB

Consider an initial state with  $N/2$  spins excited and  $N/2$  unexcited

$$|\Psi_{initial}\rangle = |\underbrace{\uparrow \dots \uparrow}_{N/2} \underbrace{\downarrow \dots \downarrow}_{N/2}\rangle = \sum_{S=0}^{N/2} a_S |S_{tot} = S, m_{tot} = 0\rangle$$

$$m_{tot} = 0 \longrightarrow S_{tot} = \begin{cases} 0 & \text{dark} \\ 1 & \text{emits 1 photon} \rightarrow m_{tot} = -1 \\ 2 & \text{emits 2 photons} \rightarrow m_{tot} = -2 \\ 3 & \text{emits 3 photons} \rightarrow m_{tot} = -2 \\ \vdots & \vdots \\ N/2 & \text{emits } N/2 \text{ photons} \rightarrow m_{tot} = -N/2 \end{cases}$$

Probability of observing  $p$  photons is  $|a_p|^2$

Claim: Null observation collapses spins onto a 'strong RVB' state

# RVB construction

Rule for constructing the strong RVB state

- ▶ Arrange  $\uparrow$  spins in top row and  $\downarrow$  spins in bottom row
- ▶ Place dimers (singlets) connecting each site in top row to a site in bottom row
- ▶ Superpose all such configurations *symmetrically* and *in-phase*

$$\hat{P}_0 \left| \begin{array}{c} \uparrow \uparrow \uparrow \\ \downarrow \downarrow \downarrow \end{array} \right\rangle \sim \frac{1}{3\sqrt{2}} \left[ \begin{array}{c} | \text{III} \rangle + | \text{XII} \rangle + | \text{XIX} \rangle \\ + | \text{XIX} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle \end{array} \right]$$

$$\hat{P}_0 \left| \begin{array}{c} \uparrow \uparrow \uparrow \uparrow \\ \downarrow \downarrow \downarrow \downarrow \end{array} \right\rangle \sim \frac{1}{6\sqrt{5}} \left[ \begin{array}{c} | \text{IIII} \rangle + | \text{XIII} \rangle + | \text{XIX} \rangle + | \text{XXI} \rangle \\ + | \text{XIX} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle \\ + | \text{XIX} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle \\ + | \text{XIX} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle \\ + | \text{XIX} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle + | \text{XXI} \rangle \end{array} \right]$$

Note the symmetry under in-row permutations.

# Proof of RVB Nature of dark state

Key ingredient: symmetry under in-row permutations

- ▶ Lemma 1: A state of  $M$  spins that is symmetric under any permutation of the  $M$  constituent spins must necessarily have  $S_{tot} = M/2$ , i.e., it has the maximal total angular momentum quantum number. Conversely, if a state of  $M$  spins has  $S_{tot} = M/2$ , it is symmetric under any permutation of the constituent spins.
- ▶ Lemma 2: For the system with  $M$  spins, a quantum state with  $S_{tot} = M/2$  is uniquely defined by its  $m_{tot}$  quantum number, i.e., a state given by  $|S_{tot} = M/2, m\rangle$  is unique.
- ▶ Lemma 3: For the system with  $M$  spins, the projection operator onto the subspace with fixed  $S_{tot}$  quantum number is symmetric under permutations. This can be seen by explicit construction. We have

$$\hat{P}_{S=\Sigma} = \prod_{S \neq \Sigma} \frac{\hat{S}_{tot}^2 - S(S+1)}{\Sigma(\Sigma+1) - S(S+1)}. \quad (1)$$

# Proof of RVB Nature of dark state

- ▶ The dark state obtained from null emission is given by

$$|\Psi_{dark}\rangle \sim \hat{P}_{S=0}|\Psi_{initial}\rangle$$

- ▶ This state is symmetric under in-row permutations  $\rightarrow$

$$|\Psi_{dark}\rangle = \sum_{\lambda=0}^{N/2} C_{\lambda} |S_{tot} = N/4, m_{tot} = N/4 - \lambda\rangle_t \otimes |S_{tot} = N/4, m_{tot} = \lambda - N/4\rangle_b.$$

- ▶ The coefficients  $C_{\lambda}$  is simply the Clebsch Gordan coefficient  $C\{j_1 = N/4, m_1 = N/4 - \lambda; j_2 = N/4, m_2 = N/4 + \lambda; j_3 = 0\}$

# Proof of RVB Nature of dark state

- ▶ The RVB state also has in-row permutation symmetry  $\rightarrow$  if decomposed into row wavefunctions, each row-wavefunction must have  $S_{tot} = N/4$
- ▶ We explicitly expand the wavefunction in the form

$$|\Psi_{RVB}\rangle = \sum_{\lambda=0}^{N/2} D_{\lambda} |S_{tot} = N/4, m_{tot} = N/4 - \lambda\rangle_t \otimes |S_{tot} = N/4, m_{tot} = \lambda - N/4\rangle_b$$

- ▶ By explicit evaluation and regrouping of terms, we see that  $D_{\lambda} = C_{\lambda}$ , i.e., the proposed RVB state and the dark state are identical!
- ▶ Probability for null emission:  
 $\langle \Psi_{initial} | \Psi_{RVB} \rangle|^2 = |D_{\lambda=0}|^2 = (N/2 + 1)^{-1} \sim N^{-1}$
- ▶ Probability for creating an RVB state of 20 spins  $\sim 10\% \rightarrow$  90% of the runs must be discarded

## Entanglement in RVB state

Figure 1 consists of three parts labeled (a), (b), and (c). Part (a) shows three vertical gray bars, each with a blue arrow pointing up at the top and a blue arrow pointing down at the bottom. Part (b) shows three vertical blue bars, each with a small orange dot at the top and a small orange dot at the bottom. Part (c) shows a large bracket containing six states, each with three blue bars and orange dots. The states are: 1) three vertical bars with dots at top and bottom; 2) two vertical bars with dots at top and bottom, and one horizontal bar with dots at left and right; 3) one vertical bar with dots at top and bottom, and two horizontal bars with dots at left and right; 4) three horizontal bars with dots at left and right; 5) two horizontal bars with dots at left and right, and one vertical bar with dots at top and bottom; 6) one horizontal bar with dots at left and right, and two vertical bars with dots at top and bottom. The entire set of states is multiplied by the factor  $\frac{1}{3\sqrt{2}}$ .

Definition: an entangled state is one that cannot be written as a direct product wavefunction

A fixed valence bond configuration: cannot be written as a direct product of spin wavefunctions. However, it can be written as a direct product of dimers  $\rightarrow$  not entangled in this sense

(a) 
$$\frac{1}{\alpha_3} \left[ \begin{array}{c} | \text{III} \rangle + | \text{XI} \rangle + | \text{X*} \rangle \\ | \text{IX} \rangle + | \text{XX} \rangle + | \text{X*} \rangle \end{array} \right]$$

(b) 

(c) 

Entanglement entropy from row-wise decomposition  
 $= \log(1 + N/2)$ , grows with  $N$

# Summary

- ▶ Initialise  $N$  spins in a direct product state within a lossy cavity
- ▶ Measure number of photons emitted
- ▶ Null observation collapses wavefunction onto an RVB state
- ▶ Route to synthesize entangled pure states of 20 or more constituents

$$\hat{\mathcal{P}}_0 \left| \begin{array}{c} \uparrow \uparrow \uparrow \\ \downarrow \downarrow \downarrow \end{array} \right\rangle \sim \frac{1}{3\sqrt{2}} \left[ \begin{array}{l} \left| \begin{array}{c} \text{III} \\ \text{III} \end{array} \right\rangle + \left| \begin{array}{c} \text{XI} \\ \text{XI} \end{array} \right\rangle + \left| \begin{array}{c} \text{X} \\ \text{X} \end{array} \right\rangle \\ + \left| \begin{array}{c} \text{IX} \\ \text{IX} \end{array} \right\rangle + \left| \begin{array}{c} \text{XX} \\ \text{XX} \end{array} \right\rangle + \left| \begin{array}{c} \text{X} \\ \text{X} \end{array} \right\rangle \end{array} \right]$$

# Collapse by positive photon observation

$$|\psi_{initial}\rangle = |\underbrace{\uparrow \dots \uparrow}_{N/2} \underbrace{\downarrow \dots \downarrow}_{N/2}\rangle = \sum_{S=0}^{N/2} a_S |S_{tot} = S, m_{tot} = 0\rangle$$

$$m_{tot} = 0 \implies$$

$S_{tot} =$	$\left\{ \begin{array}{l} 0 \\ 1 \\ 2 \\ 3 \\ \vdots \\ N/2 - 1 \\ N/2 \end{array} \right.$	$\left  \begin{array}{l} \text{dark} \\ \text{emits 1 photon} \\ \text{emits 2 photons} \\ \text{emits 3 photons} \\ \vdots \\ \text{emits } N/2 - 1 \text{ photons} \\ \text{emits } N/2 \text{ photons} \end{array} \right $	$\left\{ \begin{array}{l} \text{undoped RVB} \\ 2 \text{ spinons} \\ 4 \text{ spinons} \\ 6 \text{ spinons} \\ \vdots \\ N - 2 \text{ spinons} \\ \text{Non - RVB : }  \downarrow \dots \downarrow\rangle. \end{array} \right.$
-------------	---	--	---

# Incipient superconductivity and RVB states

If we do not measure the photon number, we obtain a mixed state of spins

$$\hat{\rho}_{spin} = \text{Tr}_{ph.} \hat{\rho} = \sum_{p=0}^{N/2} \alpha_p |\Psi_p\rangle \langle \Psi_p| \quad (2)$$

– a state with fluctuating (even) spinon number – incipient superconductivity  $\sim$  finite size system with superconducting correlations

For large  $N$ , a small spin-spin interaction may suffice to generate coherence between different number sectors  $\implies$  signatures of superconductivity!
